Interval-valued Fuzzy-Rough Feature Selection in Datasets with Missing Values

Richard Jensen and Qiang Shen

Abstract—One of the many successful applications of rough set theory has been to the area of feature selection. The rough set principle of using only the supplied data and no other information has many benefits, where most other methods require supplementary knowledge. Fuzzy-rough set theory has recently been proposed as an extension of this, in order to better handle the uncertainty present in real data. However, following this approach, there has been no investigation (theoretical or otherwise) into how to deal with missing values effectively, another problem encountered when using real world data. This paper proposes an extension of the fuzzy-rough feature selection methodology, based on interval-valued fuzzy sets, as a means to counter this problem via the representation of missing values in an intuitive way.

I. INTRODUCTION

Lately there has been great interest in developing computational intelligence methodologies which are capable of dealing with imprecision and uncertainty, and the resounding amount of research currently being done in the areas related to fuzzy and rough sets [13] is representative of this. The success of rough set theory is due in part to three aspects of the theory. Firstly, only the facts hidden in data are analysed. Secondly, no additional information about the data is required for data analysis such as thresholds or expert knowledge on a particular domain. Thirdly, it finds a minimal knowledge representation for data. As rough set theory handles only one type of imperfection found in data, it is complementary to other concepts for the purpose, such as fuzzy set theory. The two fields may be considered analogous in the sense that both can tolerate inconsistency and uncertainty - the difference being the type of uncertainty and their approach to it; fuzzy sets are concerned with vagueness, rough sets are concerned with indiscernibility.

Many deep relationships have been established and more so, most of the recent studies have concluded at this complementary nature of the two methodologies, especially in the context of granular computing [1]. Therefore, it is desirable to extend and hybridize the underlying concepts to deal with additional aspects of data imperfection. Such developments offer a high degree of flexibility and provide robust solutions and advanced tools for data analysis [9]. However, there has been no investigation into how such hybridizations may model and cope with missing values in datasets. This is a severely limiting factor for the application of these powerful techniques. In this paper, a further extension to fuzzy-rough set theory is proposed, interval-valued fuzzy-rough sets, in

order to alleviate this problem. As a result of this, a new feature selection method is developed that not only handles missing values, but also alleviates the problem of defining overly-specific type-1 fuzzy similarity relations (i.e. those with crisp membership functions) through the use of interval-valued fuzzy sets [3], [11].

The remainder of this paper is structured as follows. The theoretical background is given in section II, providing necessary details for fuzzy sets, interval-valued fuzzy sets, rough sets and fuzzy-rough sets. Section III focuses on the proposed approach, interval-valued fuzzy-rough feature selection. Initial experimental results that demonstrate the potential of the approach are presented in section IV. Finally, section V concludes the paper and outlines some ideas for future work.

II. THEORETICAL BACKGROUND

A. Fuzzy Sets

Recall that a fuzzy set [15] in \mathbb{U} is an $\mathbb{U} \rightarrow [0, 1]$ mapping, while a fuzzy relation in \mathbb{U} is a fuzzy set in $\mathbb{U} \times \mathbb{U}$. For all y in \mathbb{U} , the R -foreset of y is the fuzzy set Ry defined by $\mu_{Ry}(x) = \mu_R(x, y)$ for all x in \mathbb{U} . If R is reflexive and symmetric, i.e., $\mu_R(x, x) = 1$ and $\mu_R(x, y) = \mu_R(y, x)$ hold for all x and y in \mathbb{U} , then R is called a fuzzy tolerance relation.

Fuzzy logic connectives play an important role in the hybridisation process. A triangular norm (t-norm for short) \mathcal{T} is any increasing, commutative and associative $[0, 1]^2 \rightarrow [0, 1]$ mapping satisfying $\mathcal{T}(1, x) = x$, for all x in $[0, 1]$. Common examples of t-norms include the minimum, the product and \mathcal{T}_L defined by $\mathcal{T}_L(x, y) = \max(0, x + y - 1)$ for x, y in $[0, 1]$. An implicator is any $[0, 1]^2 \rightarrow [0, 1]$ -mapping \mathcal{I} that is decreasing in its first, and increasing in its second component, and that satisfies $\mathcal{I}(0, 0) = 1$ and $\mathcal{I}(1, x) = x$, for all x in $[0, 1]$.

1) *Interval-valued Fuzzy Sets*: An interval-valued fuzzy set \tilde{A} in \mathbb{U} is an ordered triple of the form

$$\tilde{A} = \{ \langle x, \mu_{A_*}(x), \mu_{A^*}(x) \rangle | x \in \mathbb{U} \} \quad (1)$$

where $\mu_{A_*}(x), \mu_{A^*} \in [0, 1]$ are the lower and upper membership functions which satisfy $0 \leq \mu_{A_*}(x) \leq \mu_{A^*}(x) \leq 1$, $\forall x \in \mathbb{U}$. The lower and upper membership functions correspond to the lower and upper bound of a closed interval describing the membership of x to \tilde{A} .

Richard Jensen (email: rkj@aber.ac.uk) and Qiang Shen (email: qqs@aber.ac.uk), are with the Department of Computer Science, Aberystwyth University, Aberystwyth, Wales, UK.

B. Rough Sets

Let $I = (\mathbb{U}, \mathbb{A})$ be an information system, where \mathbb{U} is a non-empty set of finite objects (the universe of discourse) and \mathbb{A} is a non-empty finite set of attributes such that $a : \mathbb{U} \rightarrow V_a$ for every $a \in \mathbb{A}$. V_a is the set of values that attribute a may take. With any $P \subseteq \mathbb{A}$ there is an associated equivalence relation $IND(P)$:

$$IND(P) = \{(x, y) \in \mathbb{U}^2 \mid \forall a \in P, a(x) = a(y)\} \quad (2)$$

The partition of \mathbb{U} , generated by $IND(P)$ is denoted $\mathbb{U}/IND(P)$ (or \mathbb{U}/P for simplicity) and can be calculated as follows:

$$\mathbb{U}/IND(P) = \otimes \{\mathbb{U}/IND(\{a\}) \mid a \in P\}, \quad (3)$$

where \otimes is specifically defined as follows for sets A and B :

$$A \otimes B = \{X \cap Y \mid X \in A, Y \in B, X \cap Y \neq \emptyset\} \quad (4)$$

If $(x, y) \in IND(P)$, then x and y are indiscernible by attributes from P . The equivalence classes of the P -indiscernibility relation are denoted $[x]_P$.

Let $X \subseteq \mathbb{U}$. X can be approximated using only the information contained within P by constructing the P -lower and P -upper approximations of X :

$$\underline{P}X = \{x \in \mathbb{U} \mid [x]_P \subseteq X\} \quad (5)$$

$$\overline{P}X = \{x \in \mathbb{U} \mid [x]_P \cap X \neq \emptyset\} \quad (6)$$

The tuple $(\underline{P}X, \overline{P}X)$ is called a rough set.

1) *Feature Selection*: Let P and Q be sets of attributes inducing equivalence relations over \mathbb{U} , then the positive region can be defined as:

$$POS_P(Q) = \bigcup_{X \in \mathbb{U}/Q} \underline{P}X \quad (7)$$

The positive region contains all objects of \mathbb{U} that can be classified to classes of \mathbb{U}/Q using the information in attributes P . Based on this definition, dependencies between attributes can be determined. For $P, Q \subseteq \mathbb{A}$, it is said that Q depends on P in a degree k ($0 \leq k \leq 1$), denoted $P \Rightarrow_k Q$, if

$$k = \gamma_P(Q) = \frac{|POS_P(Q)|}{|\mathbb{U}|} \quad (8)$$

The reduction of attributes is achieved by comparing equivalence relations generated by sets of attributes. Attributes are removed so that the reduced set provides the same predictive capability of the decision attribute as the original. A *reduct* R_{min} is defined as a minimal subset R of the initial attribute set \mathbb{C} such that for a given set of attributes D , $\gamma_R(\mathbb{D}) = \gamma_{\mathbb{C}}(\mathbb{D})$. From the literature, R is a minimal subset if $\gamma_{R-\{a\}}(\mathbb{D}) \neq \gamma_R(\mathbb{D})$ for all $a \in R$. This means that no attributes can be removed from the subset without affecting the dependency degree. Hence, a minimal subset by this definition may not be the *global* minimum (a reduct of smallest cardinality). The goal of rough set-based feature selection is to discover reducts of smallest cardinality.

C. Fuzzy-Rough Sets

Fuzzy-rough sets [7] encapsulate the related but distinct concepts of vagueness (for fuzzy sets) and indiscernibility (for rough sets), both of which occur as a result of uncertainty in knowledge

Definitions for the fuzzy lower and upper approximations can be found in [14], where a \mathcal{T} -transitive fuzzy similarity relation is used to approximate a fuzzy concept X :

$$\mu_{\underline{R}_P X}(x) = \inf_{y \in \mathbb{U}} \mathcal{I}(\mu_{R_P}(x, y), \mu_X(y)) \quad (9)$$

$$\mu_{\overline{R}_P X}(x) = \sup_{y \in \mathbb{U}} \mathcal{T}(\mu_{R_P}(x, y), \mu_X(y)) \quad (10)$$

Here, \mathcal{I} is a fuzzy implicator and \mathcal{T} a t-norm. R_P is the fuzzy similarity relation induced by the subset of features P :

$$\mu_{R_P}(x, y) = \mathcal{T}_{a \in P} \{\mu_{R_a}(x, y)\} \quad (11)$$

$\mu_{R_a}(x, y)$ is the degree to which objects x and y are similar for feature a , and may be defined in many ways, for example:

$$\mu_{R_a}(x, y) = 1 - \frac{|a(x) - a(y)|}{|a_{max} - a_{min}|} \quad (12)$$

$$\mu_{R_a}(x, y) = \max\left(\min\left(\frac{(a(y) - (a(x) - \sigma_a))}{\sigma_a}, \frac{((a(x) + \sigma_a) - a(y))}{\sigma_a}, 0\right)\right) \quad (13)$$

where σ_a^2 is the variance of feature a . As these relations do not necessarily display \mathcal{T} -transitivity, the fuzzy transitive closure can be computed for each attribute. The choice of relation is largely determined by the intended application. For feature selection, a relation such as (13) may be appropriate as this permits only small differences between attribute values of differing objects. For classification tasks, a more gradual and inclusive relation such as (12) should be used.

1) *Feature Selection*: In a similar way to the original crisp rough set approach, the fuzzy positive region can be defined as [10]:

$$\mu_{POS_P(\mathbb{D})}(x) = \sup_{X \in \mathbb{U}/\mathbb{D}} \mu_{\underline{R}_P X}(x) \quad (14)$$

An important issue in data analysis is discovering dependencies between attributes. The fuzzy-rough degree of dependency of \mathbb{D} on the attribute subset P can be defined in the following way:

$$\gamma'_P(\mathbb{D}) = \frac{\sum_{x \in \mathbb{U}} \mu_{POS_P(\mathbb{D})}(x)}{|\mathbb{U}|} \quad (15)$$

A fuzzy-rough reduct R can be defined as a minimal subset of features that preserves the dependency degree of the entire dataset, i.e. $\gamma'_R(\mathbb{D}) = \gamma'_{\mathbb{C}}(\mathbb{D})$. Based on this, a fuzzy-rough greedy hill-climbing algorithm can be constructed that uses equation (15) to gauge subset quality. In [10], it has been shown that the dependency function is monotonic and that fuzzy discernibility matrices may also be used to discover reducts. However, there is no mechanism for modeling missing values in this framework, and is therefore limited in its application to real world datasets. This motivates the work proposed in the following section.

III. INTERVAL-VALUED FRFS

Central to traditional fuzzy-rough feature selection is the fuzzy tolerance relation. From this, the fuzzy-rough lower approximations are constructed which then form the fuzzy positive regions utilised in the degree of dependency measure. Thus, the starting point for the process, type-1 fuzzy tolerance, is critical for its success. It is recognised that type-1 approaches are unable to address particular types of uncertainty due to their requirement of totally crisp membership functions [12]. An interval-valued approach may therefore be able to better handle this uncertainty and at the same time model the uncertainty inherent in missing values. Currently, there is no way to handle such values in fuzzy-rough set theory. Thus, the starting point for the proposed work is the interval-valued tolerance relation $\widetilde{R}_a(x, y)$. The constituent fuzzy relations for individual attributes can be defined via an upper (R_{a^*}) and lower (R_{a*}) membership function, for example:

$$\mu_{R_{a*}}(x, y) = 1 - \left(\frac{|a(x) - a(y)|}{|a_{\max} - a_{\min}|} \right)^m \quad (16)$$

$$\mu_{R_{a^*}}(x, y) = 1 - \frac{|a(x) - a(y)|}{|a_{\max} - a_{\min}|} \quad (17)$$

for $m \in (0, 1)$. If $m = 1$, $\widetilde{R}_a(x, y)$ degenerates to a standard type-1 fuzzy tolerance relation. As with type-1 fuzzy-rough feature selection, composition of relations is achieved by conjunctively combining the individual fuzzy relations \widetilde{R}_a with a t-norm \mathcal{T} :

$$\begin{aligned} \mu_{\widetilde{R}_P}(x, y) &= \mathcal{T}_{a \in P} \{ \mu_{\widetilde{R}_a}(x, y) \} \\ &= [\mathcal{T}_{a \in P} \{ \mu_{R_{a*}}(x, y) \}, \mathcal{T}_{a \in P} \{ \mu_{R_{a^*}}(x, y) \}] \end{aligned} \quad (18)$$

Based on the definitions above, the interval-valued P -lower and P -upper approximation of a concept \widetilde{X} are here defined as

$$\mu_{\widetilde{R}_P \widetilde{X}}(x) = \inf_{y \in \mathbb{U}} \mathcal{I}(\mu_{\widetilde{R}_P}(x, y), \mu_{\widetilde{X}}(y)) \quad (19)$$

$$\mu_{\widetilde{R}_P \widetilde{X}}(x) = \sup_{y \in \mathbb{U}} \mathcal{T}(\mu_{\widetilde{R}_P}(x, y), \mu_{\widetilde{X}}(y)) \quad (20)$$

where $\widetilde{R}_P(x, y)$ is an interval-valued fuzzy tolerance relation. The tuple $(\widetilde{R}_P \widetilde{X}, \widetilde{R}_P \widetilde{X})$ is called an interval-valued fuzzy-rough set.

The underlying interval-valued tolerance relation can be modified in order to model the uncertainty resulting from missing values. If an object contains a missing value for a particular feature, then the resulting degree of similarity with other objects is unknown. In an interval-valued context, this can be modeled by returning the unit interval when an attribute value is missing for one or both objects:

$$\mu_{\widetilde{R}_a}(x, y) = \begin{cases} \mu_{R_a}(x, y) & \text{if } a(x), a(y) \neq *, \\ [0, 1] & \text{otherwise} \end{cases} \quad (21)$$

where missing values are denoted by *. Again, relations are composed via a t-norm. The resulting interval-valued lower

and upper approximations can then be used to gauge subset quality.

A. Lower Approximation-based FS

The interval-valued lower approximation can be defined as follows:

$$\begin{aligned} \mu_{\widetilde{R}_P \widetilde{X}}(x) &= \inf_{y \in \mathbb{U}} \mathcal{I}(\mu_{\widetilde{R}_P}(x, y), \mu_{\widetilde{X}}(y)) \\ &= \inf_{y \in \mathbb{U}} [\mathcal{I}(\mu_{R_{P^*}}(x, y), \mu_{X^*}(y)), \\ &\quad \mathcal{I}(\mu_{R_{P*}}(x, y), \mu_{X^*}(y))] \end{aligned} \quad (22)$$

This provides a measure of the certainty of membership of an object to a given concept \widetilde{X} as a result of the underlying uncertainty in the similarity between this object and others in the universe. Note that the use of $\mu_{R_{P^*}}$ and $\mu_{R_{P*}}$ is reversed due to the properties of fuzzy implication. The resulting interval is a lower and upper bound on the true membership degree. Based on this, the interval-valued positive region is defined:

$$\mu_{\widetilde{POS}_P(\mathbb{D})}(x) = \sup_{\widetilde{X} \in \mathbb{U}/\mathbb{D}} \mu_{\widetilde{R}_P \widetilde{X}}(x) \quad (23)$$

From this, the interval-valued degree of dependency of decision features \mathbb{D} on a feature subset P is defined as:

$$\begin{aligned} \widetilde{\gamma}_P(\mathbb{D}) &= \frac{|\widetilde{POS}_P(\mathbb{D})|}{|\mathbb{U}|} \\ &= \left[\sum_{y \in \mathbb{U}} \frac{POS_{P^*}(\mathbb{D})(y)}{|\mathbb{U}|}, \sum_{y \in \mathbb{U}} \frac{POS_{P^*}^*(\mathbb{D})(y)}{|\mathbb{U}|} \right] \end{aligned} \quad (24)$$

In [6], a normalised version of dependency was introduced for FRFS. The equivalent interval-valued normalised version is as follows:

$$\begin{aligned} \widetilde{\gamma}_P(\mathbb{D}) &= \frac{|\widetilde{POS}_P(\mathbb{D})|}{|\widetilde{POS}_C(\mathbb{D})|} \\ &= \left[\frac{1}{|\mathbb{U}|} \sum_{y \in \mathbb{U}} \frac{POS_{P^*}(\mathbb{D})(y)}{POS_{C^*}(\mathbb{D})(y)}, \frac{1}{|\mathbb{U}|} \sum_{y \in \mathbb{U}} \frac{POS_{P^*}^*(\mathbb{D})(y)}{POS_{C^*}^*(\mathbb{D})(y)} \right] \end{aligned} \quad (25)$$

Here, $\widetilde{\gamma}_P(\mathbb{D})$ is an interval $[\gamma_{P^*}(\mathbb{D}), \gamma_{P^*}^*(\mathbb{D})]$ that describes the extent to which the features in P are predictive of the decision feature(s). P is called a fuzzy decision superreduct to degree α if $\widetilde{\gamma}_P(\mathbb{D}) \geq \alpha$, and a fuzzy decision reduct to degree α if moreover for all $P' \subset P$, $\widetilde{\gamma}_{P'}(\mathbb{D}) < \alpha$. Note that if a type-1 fuzzy tolerance relation is used, then these definitions degenerate to their traditional fuzzy-rough counterparts. Core features (i.e. those that cannot be removed without introducing inconsistencies) may be determined by considering the change in dependency of the full set of conditional features when individual attributes are removed:

$$Core(\mathbb{C}) = \{a \in \mathbb{C} | \widetilde{\gamma}_{\mathbb{C}-\{a\}}(\mathbb{D}) \neq \widetilde{\gamma}_{\mathbb{C}}(\mathbb{D})\} \quad (26)$$

Subset search can be conducted by whichever mechanism is appropriate; for example, greedy hill-climbing, genetic algorithms, ant colony optimization [8] etc. Here, the standard

greedy hill-climbing approach is adopted. The dependency degree is monotonic in both the lower and upper bounds, and so search continues until $[1, 1]$ is reached (no uncertainty) or there is no improvement in dependency.

B. Boundary Region-based FS

Most approaches to crisp rough and fuzzy-rough FS use only the lower approximation for the evaluation of feature subsets. The lower approximation contains information regarding the extent of certainty of object membership to a given concept. However, the upper approximation contains information regarding the degree of uncertainty of objects and hence this information can be used to discriminate between subsets. For example, two subsets may result in the same lower approximation but one subset may produce a smaller upper approximation. This subset will be more useful as there is less uncertainty concerning objects within the boundary region (the difference between upper and lower approximations). The interval-valued upper approximation can be defined as:

$$\begin{aligned}\mu_{\widetilde{R_P X}}(x) &= \sup_{y \in \mathbb{U}} \mathcal{T}(\mu_{\widetilde{R_P}}(x, y), \mu_{\widetilde{X}}(x)) \\ &= \sup_{y \in \mathbb{U}} [\mathcal{T}(\mu_{R_P^*}(x, y), \mu_{X^*}(x)), \\ &\quad \mathcal{T}(\mu_{R_P^*}(x, y), \mu_{X^*}(x))] \quad (27)\end{aligned}$$

The fuzzy-rough boundary region for a fuzzy concept X may thus be defined:

$$\mu_{\widetilde{BND_P(X)}}(x) = \mu_{\widetilde{R_P X}}(x) - \mu_{\widetilde{R_P X}}(x) \quad (28)$$

As the search for an optimal subset progresses, the object memberships to the boundary region for each concept diminishes until a minimum is achieved. For crisp rough set FS, the boundary region will be zero for each concept when a reduct is found. This may not necessarily be the case for interval-valued fuzzy-rough FS due to the additional uncertainty involved. The uncertainty for a concept X using features in P can be calculated as follows:

$$\begin{aligned}\widetilde{U_P(X)} &= \frac{\sum_{x \in \mathbb{U}} \mu_{\widetilde{BND_P(X)}}(x)}{|\mathbb{U}|} \quad (29) \\ &= \left[\sum_{x \in \mathbb{U}} \frac{BND_{P^*}(X)(x)}{|\mathbb{U}|}, \sum_{x \in \mathbb{U}} \frac{BND_{P^*}(X)(x)}{|\mathbb{U}|} \right]\end{aligned}$$

This is the average extent to which objects belong to the fuzzy boundary region for the concept X . The total uncertainty degree for all concepts, given a feature subset P is defined as:

$$\widetilde{\lambda_P(Q)} = \frac{\sum_{X \in \mathbb{U}/Q} \widetilde{U_P(X)}}{|\mathbb{U}/Q|} \quad (30)$$

It is this measure, $\widetilde{\lambda_P(Q)}$, that can be used to gauge subset quality. When the measure is minimized for a given subset P , then the subset is a (super)reduct for the decision system.

It is shown in the Appendix that $\gamma'_P(Q) = 1 - \lambda_P(Q)$ for decision systems with two decision concepts (classes), and so the reductions achieved using both measures will be identical in this case. This will also be true of the interval-valued counterparts.

C. Discernibility Function

The fuzzy interval-valued tolerance relations that represent objects' approximate equality can be used to extend the classical discernibility function. For each combination of conditional attributes, an interval is obtained indicating how well these attributes maintain the discernibility, relative to the decision attribute, between all objects.

$$\widetilde{f}(P) = \mathcal{T}(\underbrace{\widetilde{c_{ij}}(P)}_{1 \leq i < j \leq |\mathbb{U}|}) \quad (31)$$

with

$$\widetilde{c_{ij}}(P) = \mathcal{I}(\underbrace{\mathcal{T}(\mu_{\widetilde{R_a}}(x_i, x_j), \mu_{\widetilde{R_d}}(x_i, x_j))}_{a \in P}) \quad (32)$$

Alternatively, rather than taking a minimum operation in Eq. (31), one can also consider the average over all object pairs, i.e.,

$$\widetilde{g}(P) = \frac{2 \cdot \sum_{1 \leq i < j \leq n} \widetilde{c_{ij}}(P)}{n(n-1)} \quad (33)$$

This formula is less rigid than equation (31), which produces the value 0 as soon as one of the c_{ij} equals 0.

IV. EXPERIMENTATION

To test the robustness of the proposed approaches in the presence of missing values five benchmark datasets were used, obtained from [2] and containing no missing values initially. Values were randomly corrupted to become missing based on a supplied probability of mutation, and the three interval-valued FRFS algorithms run, using $m = 0.9$ for the tolerance relation. This was carried out ten times for each dataset. Table I shows the dataset details as well as the probabilities of value corruption and the resulting ranges of numbers of missing values; e.g. for the water 2 dataset and probability of mutation 0.0005, datasets were produced with 4 to 14 missing values present. For comparison, the type-1 FRFS algorithm was run on the original, uncorrupted data. As the corruption probability increases, the amount of missing data greatly increases, with the final column showing a degree of missing values not often seen in real data but useful to test the robustness of the approach.

JRip [4] was employed for the purpose of evaluating the resulting subsets. JRip learns propositional rules by repeatedly growing rules and pruning them. During the growth phase, features are added greedily until a termination condition is satisfied. Features are then pruned in the next phase subject to a pruning metric. Once the ruleset is generated, a further optimization is performed where classification rules

Olitos	60.83	60.83	61.16	62.67	62.83	64.58

are evaluated and deleted based on their performance on randomized data.

The resulting reduct sizes (averaged over repeated runs and inclusive of the decision feature) can be seen in tables II, III and IV. All discovered reducts produced a type-1 dependency degree of 1 for the uncorrupted data and hence were all fuzzy-rough reducts. This shows the resilience of the approach when faced with corrupted data, but may not necessarily be the case in general as it will depend on the extent of missing values and similarity relation chosen. For small numbers of missing values, the algorithms manage to locate identical or equivalent reducts to the original type-1 approach (which was applied to the uncorrupted data). As the extent of data corruption increases, the task becomes more difficult, with more features being selected by all approaches to compensate for the lack of information but still producing valid fuzzy-rough reducts.

For the datasets with two decision classes, the lower approximation-based method and the boundary region-based method performed identically, as expected. These methods were more consistent in the reducts found, whereas more variety was observed with the fuzzy discernibility approach, which indicates the latter's greater sensitivity to corrupted data.

Tables V, VI and VII show the resulting average classifi-

cation accuracies of the feature subsets using JRip and 10-fold cross validation. The column labeled 'Type-1' gives the classification accuracy of the corresponding type-1 approach on the uncorrupted data. It can be seen from these results that the interval-valued methods are capable of finding reducts of a similar high quality to those of their type-1 counterparts, in the presence of missing values. Even with a large amount of data corruption, the methods can find good, if slightly larger, subsets.

V. CONCLUSION

This paper proposed an interval-valued approach to fuzzy-rough feature selection that successfully handles the uncertainty that cannot be modeled by a type-1 approach. In particular, this method can handle missing values effectively

TABLE VI
CLASSIFICATION ACCURACIES: BOUNDARY REGION-BASED METHOD

Dataset	Type-1 method	Average classification accuracy (%)				
		0.0005	0.001	0.005	0.01	0.1
Heart	78.52	78.52	78.52	78.71	77.82	78.71

and in an intuitive way. Three subset quality measures were developed based on this framework: lower approximation-based, boundary region-based and discernibility function-based evaluation. Future work will involve further experimental investigations, particularly to see if the trend observed in this paper is maintained for other datasets. This will include an analysis of the impact of the choice of similarity relation and parameter m . Additionally, the work in [5] proposed novel t-norms and implicators for interval-valued fuzzy sets; these should be of great benefit for interval-valued FRFS.

APPENDIX

Theorem 1: The lower approximation-based measure is the inverse of the boundary region-based measure for decision systems with two concepts, and so the reductions achieved will be identical. Suppose that $P \subseteq \mathbb{C}$, a is an arbitrary conditional feature that belongs to the dataset and Q is the set of decision features. Then $\gamma_P(Q) = 1 - \lambda_P(Q)$ when $|\mathbb{U}/Q| = 2$.

Proof: The boundary region-based evaluation of a concept X can be written as

$$\lambda_P(Q) = \frac{\sum_{X \in \mathbb{U}/Q} \sum_{x \in \mathbb{U}} \mu_{BND_P(X)}(x)}{|\mathbb{U}/Q| \cdot |\mathbb{U}|}$$

So,

$$\begin{aligned} 1 - \lambda_P(Q) &= \frac{\sum_{X \in \mathbb{U}/Q} \sum_{x \in \mathbb{U}} 1 - \mu_{BND_P(X)}(x)}{|\mathbb{U}/Q| \cdot |\mathbb{U}|} \\ &= \frac{\sum_{X \in \mathbb{U}/Q} \sum_{x \in \mathbb{U}} \mu_{R_P X}(x) - \mu_{\overline{R_P X}}(x) + 1}{|\mathbb{U}/Q| \cdot |\mathbb{U}|} \end{aligned}$$

The system has two decision classes, X_1 and X_2 with $\mathbb{U}/Q = \{X_1, X_2\}$. Hence, the above may be written as:

$$\frac{\sum_{x \in \mathbb{U}} (\mu_{R_P X_1}(x) - \mu_{\overline{R_P X_1}}(x) + \mu_{R_P X_2}(x) - \mu_{\overline{R_P X_2}}(x) + 2)}{2 \cdot |\mathbb{U}|} \quad (34)$$

In order to simplify this, it is necessary to show that $\mu_{\overline{R_P X_1}}(x) = 1 - \mu_{R_P X_2}(x)$ for decision systems with two

concepts.

$$\begin{aligned} \mu_{\overline{R_P X_1}}(x) &= \sup_{y \in \mathbb{U}} \mathcal{T}(\mu_{R_P}(x, y), \mu_{X_1}(y)) \\ &= 1 - (1 - \sup_{y \in \mathbb{U}} \mathcal{T}(\mu_{R_P}(x, y), \mu_{X_1}(y))) \\ &= 1 - \inf_{y \in \mathbb{U}} 1 - \mathcal{T}(\mu_{R_P}(x, y), \mu_{X_1}(y)) \\ &= 1 - \inf_{y \in \mathbb{U}} \mathcal{S}(1 - \mu_{R_P}(x, y), 1 - \mu_{X_1}(y)) \\ &= 1 - \inf_{y \in \mathbb{U}} \mathcal{I}(\mu_{R_P}(x, y), 1 - \mu_{X_1}(y)) \\ &= 1 - \inf_{y \in \mathbb{U}} \mathcal{I}(\mu_{R_P}(x, y), \mu_{X_2}(y)) \\ &= 1 - \mu_{R_P X_2}(x) \end{aligned}$$

if \mathcal{I} is an S -implicator. Putting this into equation (34) gives:

$$1 - \lambda_P(Q) = \frac{\sum_{x \in \mathbb{U}} \mu_{R_P X_1}(x) + \mu_{R_P X_2}(x)}{|\mathbb{U}|}$$

Finally, if $\mu_{X_2}(x) = 0$ (which implies $\mu_{X_1}(x) = 1$) then x will not belong to the lower approximation of this concept. Formally, $\mu_{R_P X_2}(x) = \inf_{y \in \mathbb{U}} \mathcal{I}(\mu_{R_P}(x, y), \mu_{X_2}(y))$ will be zero as $\mu_{X_2}(y) = 0$ when $x = y$. Thus

$$\begin{aligned} 1 - \lambda_P(Q) &= \frac{\sum_{x \in \mathbb{U}} \sup\{\mu_{R_P X_1}(x), \mu_{R_P X_2}(x)\}}{|\mathbb{U}|} \\ &= \gamma'_P(Q) \end{aligned}$$
